### Motivation

- How do we balance size and structure of nonzeros in a matrix to draw out key features?
- Can we make effective use of spectral information?
- κ<sub>∞</sub>(DAE) minimised over all diagonal scalings if D|A|E and E<sup>-1</sup>|A<sup>-1</sup>|D<sup>-1</sup> have equal row sums.

Balancing a Matrix

#### DA, AD, $DAD^{-1}$ , $D^{1/2}AD^{1/2}$ , $D_1AD_2$

- Choice of where to apply balance, measure of balance, method of balance.
- ▶ We choose to find D<sub>1</sub> and D<sub>2</sub> so that D<sub>1</sub>AD<sub>2</sub> has equal row/column sums.
- ▶ We use a fast Newton iteration to ensure rapid computation.

 Elements that link together almost disjoint blocks are highlighted.

## **Spectral Properties**

- $\blacktriangleright P = D_1 |A| D_2.$
- ▶ We can extend Fiedler/Perron-Frobenius theory.
- If P has k disjoint components principal singular value is repeated k times.
- $\sigma_1 = 1$ .
- Typical singular vector: permutation of  $\begin{bmatrix} 1 & \dots & 1 & 0 & \dots & 0 \end{bmatrix}^T$ .
- We can infer block entire block structure from a single singular vector.
- ► For symmetric matrices we can ensure D<sub>1</sub> = D<sub>2</sub> and work with eigenvectors.

# Algorithm

- 1. Preprocess.
- 2. Balance.
- 3. Calculate singular vector(s).
- 4. Split vector(s) to identify blocks.

◆□▶ ◆□▶ ◆三▶ ◆三▶ 三三 のへぐ

# Preprocessing

- We want to avoid scaling a matrix if it is not fully indecomposable.
- Initialise by looking for BTF and work on biggest block.
- After roughly balancing matrix try and remove strongly diagonally dominant parts of diagonal.

# Fast Balancing

- Suppose A is symmetric and DADe = e where D = diag(x).
- Rewrite:  $Ax \operatorname{diag}(x)^{-1}e = 0$ .
- Solve using Newton method. Newton step solved approximately with CG.
- Easily adapted to nonsymmetric A.
- ► Typically requires a small number of matrix-vector products using *A* and *A*<sup>*T*</sup>.

## Computing Singular Vectors

- ▶ We compute *p* = 1, 2, 3, 4, 5, ... singular vectors with eigs.
- Convergence can be slow.
- Output dependent on p and initial guess.
- We project out contribution of **e**.
- We can use information from pth vector to further project to enhance (p+1)th.

# Splitting A Vector, I

- Reorder components of vector by size.
- Identify jumps with an edge detecting algorithm (Canny filter).

- Jumps resolved at multiple levels.
- Parameter free determination of k blocks.

# Splitting A Vector, II

- We can use (p+1)th vector to refine blocks determined by first p.
- Currently we split all blocks according to information supplied by latest vector.
- To avoid countless tiny blocks we may be better refining existing blocks.
- At the end we can reconstruct matrix based on all blocks uncovered.
- For example, we can attempt to pack the diagonal with large elements.

#### Example: Matrix Blocks

-0.05

-0.1

#### Future Work, I

- We aim to provide a block structure amenable to factorisation and/or preconditioning.
- Preprocessing: there is no point in trying to scale a matrix if it is not fully indecomposable. We guard against this but would like to do better.
- Need to fully understand role of diagonal dominance in the substructures.
- ► Bi-clustering: algorithm can work with rectangular input.
- ► To what extent can we reveal useful information simply by using adjacency matrix of *A*?

# Future Work, II

- We want to fill some theoretical gaps.
- Perturbation theory for singular vectors of nearly block matrices is missing.
- How much can we using existing theory on Laplacians?
- We use a measure of cluster quality in reconstructing blocks...are we using the right one?
